Abstract

To investigate factors associated with the risk of major complications after radical prostatectomy (RP) by the open (ORP) or robot-assisted (RARP) approach for prostate cancer (PCa) in a tertiary referral center. 1062 consecutive patients submitted to RP were prospectively collected. The following outcomes were addressed: (1) overall postoperative complications: subjects with Clavien-Dindo System (CD) one through five versus cases without any complication; (2) moderate to major postoperative complications: cases with $CD < 2$ vs. ≥ 2, and 3) major post-operative complications: subjects with CDS $CD \geq 3$ vs. < 3. The association of pre-operative and intra-operative factors with the risk of postoperative complications was assessed by the logistic regression model. Overall, complications occurred in 310 out of 1062 subjects (29.2%). Major complications occurred in 58 cases (5.5%). On multivariate analysis, major complications were predicted by PCa surgery and intraoperative estimated blood loss (EBL). ORP compared to RARP increased the risk of major CD complications from 2.8 to 19.3% (OR = 8283; $p < 0.0001$). Performing ePLND increased the risk of major complications from 2.4 to 7.4% (OR = 3090; $p < 0.0001$). Assessing intraoperative blood loss, the risk of major postoperative complications was increased by BL above the third quartile when compared to subjects with intraoperative blood loss up to the third quartile (10.2% vs. 4.6%; OR = 2239; 95%CI: 1233–4064). In the present cohort, radical prostatectomy showed major postoperative complications that were independently predicted by the open approach, extended lymph-node dissection, and excessive intraoperative blood loss.

Introduction

Prostate cancer (PCa) is the most commonly diagnosed tumor and the second leading cause of death from cancer in men [1]. Although several active treatments are included

Antonio Benito Porcaro, Alessandro Tafuri and Riccardo Rizzetto contributed equally to this manuscript.

for the management of clinically localized PCa, radical prostatectomy (RP) is one of the most commonly selected treatment options that can be delivered by the open (ORP) or robot-assisted (RARP) approach [2]. RP is commonly carried out with concomitant extended pelvic lymph node dissection (ePLND) when anatomical staging of loco-regional lymph nodes is required [2]. However, prostate cancer surgery exposes patients to the risk of post-operative complications which can be classified according to Clavien–Dindo (CD) system [3, 4]. Postoperative complications prolong the length of hospital stay (LOHS) and increase the risk of readmission, thus impacting patient's wellness, physician workload, and department-costs [5, 6]. Predictors of postoperative complications may have a pivotal role in the planning of general activity and anticipating the costs to operate a urological unit [5]. The aim of this study is to investigate the risk factors associated with major postoperative complications after ORP or RARP in a tertiary referral center.

Materials and methods

Surgical technique and perioperative management

The study is retrospective with prospectively collected data. Each patient provided informed-signed consent for data collection. Five skilled and dedicated surgeons performed operations of radical prostatectomy (RP) by open (ORP) or robot-assisted (RARP) approach with or without extended pelvic lymph node dissection (ePLND).

The decision to perform RARP or ORP was made according to the surgeon expertise (robot-assisted or open surgery) and patient preference.

RARP, which was delivered by the da Vinci Robot System (Intuitive Surgical, Inc., Sunnyvale, CA, USA), was performed through the trans peritoneal approach with anterograde prostatic dissection [7]. ORP was performed according to the technique of Walsh [8]. In intermediate risk cases, the decision to perform an ePLND was based on Briganti nomogram showing a risk of lymph node invasion greater than 5% [9]. In low-risk patients, ePLND was performed based on risk factors of tumor upgrading and upstaging [10–12]. In both surgical procedures, lymph nodes were sampled according to an anatomical template including bilateral external iliac (extending proximally to the crossing of the ureter), obturator, internal iliac, Marcille's, common iliac and Cloquet's nodal stations. The external iliac LN group was dissected laterally to the genitofemoral nerve at the lateral edge of the internal iliac artery and vein from the node of Cloquet to the ureteric crossing of the internal iliac artery as previously reported [13, 14].

Five experienced surgeons performed RARP with a bladder-neck sparing technique [15]. One surgeon performed more than 500 RARPs prior to the initiation of patient enrolment and he performed 66% of the procedures included in this study. The other four surgeons had performed between 50 and 60 procedures prior to the initiation of patient enrolment.

Prophylaxis of deep venous thrombosis with low molecular weight heparin was performed in all cases who underwent ePLND and in patients with comorbid risk factors; moreover, prophylaxis was prolonged till postoperative day (POD) 28. In RARP cases, transurethral 16 French Foley bladder catheter was placed and removed on post-operative day (POD) 12 without cystography according to our standard internal protocol. After December 2017, our policy of placing a pelvic drain was discontinued according to our previous reported experience [16]. In ORP patients, a transurethral 16 French Foley bladder catheter was placed and removed on POD 12 with or without cystography according to the surgeon's decision; moreover, a pelvic drain was always placed and removed on POD 2 or 3.

Predictors of complications

Clinical, pathological, surgical, peri-operative, intra-operative parameters were identified as potential predictors of complications. Serum prostate specific antigen (PSA; ng/mL) was determined by radioimmunoassay. Age (years), body mass index (BMI; kg/m^2), total prostate volume (TPV, mL) and biopsy positive cores (BPC; percentage) were calculated for each case. Tumors were graded according to the 2014 International Society of Urologic Pathology (ISUP) [17]. Surgical specimens analyzed after 2014 were classified using the new classification and the Gleason grading group system [17, 18]. Surgical specimens evaluated between 2013 and 2014 were retrospectively classified by our dedicated pathologist after specimen review. Biopsy grade group (BGG) cancers included ISUP grade group 1–5. In appropriate cases, pelvic lymph node staging (cN) was performed by axial imaging modalities. Enlarged pelvic nodes measuring more than one centimeter in diameter were staged as cN1 disease. Axial imaging and total bone scanning was utilized to investigate the metastatic status when appropriate. Patients were classified into risk groups and staged according to the EAU guidelines recommendations on PCA [19].

Perioperative surgical risk was evaluated by the American Society of Anesthesiologists score (ASA) score system. Operating time (OT) (measured in minutes), was calculated as the interval between the first skin incision and the last skin suture in both RARP and ORP procedures. Surgical procedures were classified according to the RARP and OPR approach; moreover, ePLND (performed or not performed) was coded separately in each case. Intraoperative estimated blood loss (EBL) was measured in milliliters (mL).

Assessment of complications

Postoperative surgical complications were prospectively recorded in each patient's electronic medical record, and retrospectively collected for the present study. The events of complications were graded according to the Clavien–Dindo score system respecting Martin's criteria as recommended by EAU guidelines [3, 4]. Only patients that provided signed informed consent were followed for complications and hospital readmission (RAD) after discharge. Patients were evaluated according to an institutional protocol including patient's re-evaluation scheduled at 30, 60, 90, and 180 days after discharge by outpatient visit or phone interview by physicians.

Objectives and design of the study

The aim of the study is to evaluate factors associated with the risk of complications after RP by both open and robot-assisted approach with or without ePLND. The following outcomes were identified as follows: (1) overall postoperative complications: subjects with Clavien–Dindo System (CDS) one through five versus cases without any complication; (2) moderate to major postoperative complications: cases with CDS two through five versus zero up to one and (3) major postoperative complications: subjects with CDS three through five versus patients with CDS zero up to two.

Statistical methods

Summary statistics of the patient population and associations of factors between groups were evaluated. Data on continuous variables were reported as medians with their respective interquartile ranges (IQR) and differences between groups were analyzed by the Mann–Whitney's U test. Data on categorical variables were calculated as frequency with percentages and differences between groups were analyzed with Pearson's chi-squared test or Fisher exact test as appropriate.

The evaluation of factors associated with the risk levels of postoperative complications was assessed by the logistic regression model. Univariate models were computed first. Selection of independent variables was performed by Wald's forward regression method in evaluating multivariate models. The software used to run the analysis was IBM-SPSS version 26. All tests were two-sided with $p < 0.05$ considered to indicate statistical significance.

Results

Analysis of overall complications risk

Overall, 1062 patients were included, 891 patients underwent RARP, and 171 ORP. Demographics of the patient population and subgroups are reported in Table 1. Complications occurred in 310 patients (29.1% of cases). Extended PLND was performed in 651 patients (61.3%). Major complications occurred in 58 cases (5.5%). Statistics of postoperative complications according to the Clavien–Dindo system are detailed in Supplementary Table 1. Clinical factors associated with complications included age, tumor grade and stage, surgical approach, ePLND and blood loss. Specifically, patients who had postoperative complications were significantly older with aggressive tumors and more likely underwent ORP or ePLND with increased intraoperative blood loss. Moreover, LOHS was significantly longer in cases with complications.

The evaluation of clinical factors associated with the grades postoperative complications according to Clavien–Dindo classification is reported in Supplementary Table 2 where univariate and multivariate models are included. On multivariate analysis, the risk of overall postoperative complications were associated with ORP (odds ratio, OR = 2.038; $p < 0.0001$), ePLND (OR = 1.584; $p < 0.0001$) and EBL (OR = 1.001; $p < 0.003$); when ORP was removed, age (OR = 1.025; $p < 0.029$), ePLND (OR = 1.780; $p < 0.0001$) and EBL (OR = 1.001; $p < 0.0001$) were the independent predictors. The risk of postoperative complications greater than one compared to cases without or less than two, was predicted by ORP (OR = 2.976; $p < 0.0001$), ePLND (OR = 1.861; $p < 0.0001$) and EBL (OR = 1.001; $p < 0.0001$); when ORP was removed from the model, ePLND (OR = 2.519; $p < 0.0001$) and EBL (OR = 1.002; $p < 0.0001$) were the independent predictors of such risk. Major complications (CDS > 2) compared to cases without or less than three, were predicted only by ORP OR = 8.283; $p < 0.0001$); however, when ORP was removed from the model, ePLND (OR = 3.382; $p = 0.001$) and EBL (OR = 1.001; $p < 0.0001$) were found to be independent predictors.

Risk models predicting major postoperative complications

Adjusted risk models predicting Clavien–Dindo postoperative complications are reported in Table 2. Independent exposure variables associated with the risk of postoperative complications included surgical approach, staging of loco-regional lymph nodes and intraoperative EBL above the third quartile. Exposure variables were evaluated for

OR odds ratio; *CI* confidence interval; *RARP* robot-assisted radical prostatectomy; *ORP* open radical prostatectomy; (*), OR adjusted for extended pelvic lymph node dissection and blood lost above the third quartile; (**), OR adjusted for ORP and blood lost above the third quartile; (***), OR adjusted for blood lost above the third quartile; (^), adjusted for ORP and ePLND; (^^), adjusted for ePLND

of major Clavien–Dindo complications from 2.8 to 19.3% (OR = 8.283; 95%CI 4.780–14.355). Evaluating surgical staging of pelvic lymph nodes, ePLND when compared to cases without anatomical staging increased the risk of major postoperative complications from 2.4 to 7.4% (OR = 3.090; 95%CI 1.543–6.191). Assessing intraoperative EBL, the risk of major postoperative complications was increased by EBL above the third quartile when compared to subjects with intraoperative EBL up to the third quartile (10.2% vs. 4.6%; OR 2.239; 95%, CI 1.233–4.064). The association of the exposure variables with the risk of postoperative complications was specifically stronger for major than for overall as well as for moderate through major Clavien–Dindo complications, as shown by the odds ratio values that are detailed in Table 2.

The cohort has been further stratified in subgroups with or without ePLND, by surgical approach and blood loss up to the third quartile versus above. Distributions by subgroups are reported in Supplementary Table 3 and associations with the risk of Clavien–Dindo complications (univariate and multivariate analysis) are described in Table 3. Considering subgroups with and without ePLND, ORP referred to RARP independently associated with minor and major Clavien–Dindo complications when compared with both subjects without as well as grade 1–2 complications. Further details are illustrated in Table 3.

Discussion

Radical prostatectomy, and specifically RARP, has become the preferred PCa surgical treatment in western countries [2]. It is associated with major and minor complications that can occur over the short- and long-term after hospital discharge.

Complications after PCa surgery results in increased patient stress, physician workload and overall health cost [5].

There are few large studies dealing with complications after PCa surgery by both ORP and RARP with or without PLND. Pompe et al. showed that overall complications following PCa surgery by both ORP and RARP occurred in 1267 out of 4973 cases (25.6%) with PLND performed in 89.5% of cases; moreover, RARP was associated with less blood loss, shorter catheterization time, and lower risk of Grade II and III complications [20]. An Australian randomized study showed overall complications in only 6% of cases; however, in that study, a (limited) pelvic lymph node dissection was performed in only 36% of subjects [21]. A Sweden prospective study reported postoperative complication rates of 13.7% in 3706 patients with pelvic lymph node dissection being performed in only 448 cases (12.1%) [22]. In the present study, overall postoperative

complications occurred in 29% of cases with ePLND being performed in 61.3% of the subjects. Complication rates of our study were closer to those reported by Pompe than to the Australian or Sweden studies [19–21]. They reported a lower Clavien–Dindo grade 1 complication rate (10.8% versus 15.1%), while complication rates for other the grades substantially overlapped [20].

In this context, it appears appropriate that our results, in the setting of a tertiary referral center where PCa surgery was performed with extended PLND in more than 60% of cases, show an overall complication rate of 29%, and major Clavien–Dindo complication rate of only 5.5%.

We have shown that ORP is an independent factor which predicts high grade complication, and high-grade complications are known to be associated with hospital readmission [23, 24]. Our findings are supported by the results from multiple multi-center studies [18, 19, 23] and might be explained by lower inflammatory response after robotic surgery compared to ORP [25]. Furthermore, surgery triggers the release of cortisol due to sympathetic activation. This induces a negative feedback mechanism that attempts to recover from the stress and this recovery may be faster in RARP cases [26, 27].

Our study also showed that ePLND and excessive intraoperative EBL were independently associated with the risk of minor through moderate and up to severe Clavien–Dindo postoperative complications.

Excessive intraoperative EBL might be related to dissection of complex tumors when also ePLND is performed. Locally advanced cancers do not have a well-defined plane of dissention and hemostasis is more difficult to maintain; additionally, large tumors invading the prostate capsule are associated with a complex vascular network because of angiogenetic factors; as such, dissection and bleeding control becomes more challenging, especially in cancers located at the apex where the neuro-vascular bundle is more represented [22].

When PLND is performed during RP, especially when an extended template is adopted, complications may occur not only because of uncontrolled clamping of the lymphatic vessels but also because of small bleeding vessels originating from the muscular pelvic wall of the obturator fossa. Anatomic human variability of the vessels and the lymphatic pelvic system is also a factor that should considered during ePLND, as shown by anatomical studies investigating this subject [28]. As such, an ePLND may result in complicated lymphoceles or pelvic hematomas requiring subsequent invasive procedures. Recently, Oderda et al., showed a PLND-related complication rate of 8.9% in a large cohort of patients (*n* = 14,921 at eight European tertiary referral centers after RP and ePLND). Interestingly, it was higher in patients with pN1 (8.5% vs. 12.6, *p* < 0.001) [29].

Considering clinical T2-3 PCa patients, a challenging prostate dissection may be complicated by excessive and

uncontrolled bleeding from the prostate bed and from the small pelvic vessels. As a consequence, all these intraoperative issues result in the two main complications that occur during RP: pelvic hematomas and lymphoceles. Furthermore, when aggressive cancers of the mid-to-base regions of the prostate involve the seminal vesicles, the lymphatic network originating from the caudal and posterior parts of the gland are also involved resulting in multiple as well as and bilateral lymph node invasion [30, 31].

As such, the dissection of the posterior plane in higher stage PCa and ePLND become more challenging, because the seminal vesicles may be adherent to the posterior layer of Denovillier's fascia and the pattern of the posterior lymphatic system network is altered [32]. This might result in greater Clavien–Dindo 3a-3b complications rates, is associated with procedures related to bleeding (pelvic hematomas) and complicated pelvic lymph lymphoceles. In our study, although pelvic hematomas and lymphoceles were the most frequent complications (8.8%), only 4.2% required invasive procedures for a complete resolution (Clavien–Dindo 3a or 3b). On the other hand, many physical factors should be considered when surgical approach is discussed with PCa patients including BMI which is related to high risk of Clavien-Dindo 3 and higher complications as well as perioperative and oncological outcomes [33, 34].

Our study results have important implications in clinical practice. Patients who undergo prostate cancer surgery should be counselled on the risks and severity of postoperative complications. Surgeons can reduce the risk of postoperative complications by working on risk factors at time of surgery. Reducing the risk of postoperative complications has implications on LOHS and costs. Moderate complications as well as major Clavien–Dindo complications may require referral to a tertiary center where these complications can be safely managed. Indeed, grade 2 complications include mainly pelvic hematomas that occur during hospital stay and require close monitoring and possible radiologic intervention.

Our study has some limitations. First, although data were collected prospectively, the analysis was retrospective and, as such, suffers the limits from these kinds of studies. Second, it was not a controlled study with the bias of selection of patients.

Although our study has limits, it also has much strength. First, the data were prospectively collected. Second, it was a large single center trial where both procedures are performed by skilled and experienced surgeons. Third, it is the first study analyzing specifically the risk of major postoperative and factors predicting such risk.

Conclusions

In the present cohort, radical prostatectomy showed major postoperative complications that were independently predicted by the open approach, extended pelvic lymph-node dissection and excessive intraoperative blood loss.

Patients undergoing radical prostatectomy should be informed about the risk of post-operative complications during pre-operative counseling.

Compliance with ethical standards

Conflict of interest The authors declare that they have no conflict of interest.

Ethical approval All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki Declaration and its later amendments or comparable ethical standards.

Informed consent Informed consent was obtained from all individual participants included in the study.
