Supporting Information

ABSTRACT: Metal–organic frameworks (MOFs) show great prospect as catalysts and catalyst support materials. Yet, studies that address their dynamic, kinetic, and mechanistic role in target reactions are scarce. In this study, an exceptionally stable MOF catalyst consisting of Pt nanoparticles (NPs) embedded in a Zr-based UiO-67 MOF was subject to steady-state and transient kinetic studies involving H/D and ¹³C/¹²C exchange, coupled with operando infrared spectroscopy and density functional theory (DFT) modeling, targeting methanol formation from CO₂/H₂ feeds at 170 °C and 1–8 bar pressure. The study revealed that methanol is formed at the interface between the Pt NPs and defect Zr nodes via formate species attached to the Zr nodes. Methanol formation is mechanistically separated from the formation of coproducts CO and methane, except for hydrogen activation on the Pt NPs. Careful analysis of transient data revealed that the number of intermediates was higher than the number of open Zr sites in the MOF lattice around each Pt NP. Hence, additional Zr sites must be available for formate formation. DFT modeling revealed that Pt NP growth is sufficiently energetically favored to enable displacement of linkers and creation of open Zr sites during pretreatment. However, linker displacement during formate formation is energetically disfavored, in line with the excellent catalyst stability observed experimentally. Overall, the study provides firm evidence that methanol is formed at the interface of Pt NPs and linker-deficient Zr₆O₈ nodes resting on the Pt NP surface.

INTRODUCTION

Atmospheric levels of CO₂ have risen at an alarming rate since the first half of the 20th century following our continuous and increasing use of fossil fuels. Large cuts in CO₂ emissions can be made through utilization of greener alternatives of energy production such as solar and wind power; however, these energy sources suffer from the lack of continuity in energy output and require efficient methods for large scale energy storage in order to compete with fossil fuels.¹ One of the solutions to this problem is the production of easily stored liquid fuels with high volumetric and gravimetric energy density, such as methanol, from CO₂ and green hydrogen.² This allows for continued use of an already existing

infrastructure.³ Substantial research efforts have already been dedicated to the topic of valorizing CO₂ through hydrogenation, mainly with focus on the reverse water–gas shift (RWGS) reaction, methanation, and methanol production.^{4–13}

The product distribution of CO₂ hydrogenation varies significantly with the nature of the catalyst and operating conditions.⁷ Most prior studies show that Pt-based systems are highly selective for the RWGS reaction with a minor selectivity toward methane.^{11,14–19} In that respect, Kattel et al.¹⁸ performed a computational study of CO₂ hydrogenation over

Received: October 17, 2019

Published: December 3, 2019

Pt nanoparticles supported on SiO₂ and TiO₂. They concluded that a RWGS and CO hydrogenation path, forming CO and small amounts of methane, dominates over those materials. This finding is in agreement with experimental evidence of CO formation mainly via surface carbonates.^{15,16}

Surface formates are also observed in several studies of the RWGS^{15,16,20,21} and of water gas shift (WGS)^{22–24} reactions; however, the significance of such a pathway over Pt-based catalysts is debated. In this regard, Burch et al.²³ conducted a critical analysis of the experimental evidence for and against a formate mechanism over highly active Pt and Au WGS catalysts. They argue that most published results do not provide definite evidence for or against a formate pathway for the WGS reaction, and in the cases where reliable data are available, it is at most a minor and slow reaction pathway.

Recent studies show that, when supporting Pt on a methane producing Co-oxide catalyst, methanol selectivity is observable under favorable conditions of low temperature and elevated pressure.^{25–27} Furthermore, one prior study²⁸ demonstrated selectivity toward methanol over oxide-supported Pt where the supports alone are inactive in CO₂ hydrogenation: out of a set of catalysts producing mainly CO (>91%), Pt/ZrO₂ showed the highest CH₃OH selectivity, reaching 6% at 200 °C and 10 atm pressure.

Over the Zr–metal–organic frameworks (MOFs) UiO-66 and -67, functionalized with Cu and Cu/Zn, high methanol selectivity is ascribed to an important role of the Zr–MOF interface in the reaction. Rungtaweeworanit et al.²⁹ found XPS evidence of Zr reduction in the presence of Cu when studying Cu nanoparticles (NPs) deposited on UiO-66 as a model system for the encapsulated version of the catalyst (i.e., Cu in UiO-66). Similar findings from XPS on CuZn@UiO-67 samples with 100% bipyridine-type linkers treated with reaction gas showed indications of Zr(IV) reduction to Zr(III), suggested to be caused by H adsorption.³⁰ In combination with H₂- and CO₂-TPD results, the authors suggested participation of the Zr cluster in the reaction by means of H spillover from Cu and CO₂ adsorption on unsaturated Zr sites. When the catalyst was prepared with regular UiO-67 (i.e., biphenyl-type linkers), both the CH₃OH selectivity and catalytic stability decreased. Although the CuZn@UiO-67 material showed substantial activity in methanol formation, notably, both the crystallinity and specific surface area of the MOF were severely reduced already by the deposition of copper. Thus, the material did not exhibit the well-defined MOF structure of UiO-67 during the subsequent experiments.³⁰

In a previous contribution, we reported the CO₂ hydrogenation activity and selectivity of an exceptionally stable Pt Zr–MOF catalyst, UiO-67-Pt, at ambient pressure. This catalyst maintains its well-defined MOF structure even after long-term operation and is therefore well suited as a model system for studying the influence of the MOF framework on the reaction. In the current study, the focus is set on elucidating the role of the UiO-67 framework in CO₂ hydrogenation to methanol through a kinetic investigation. In addition to standard steady-state kinetic measurements, we employ H/D- and ¹³C/¹²C SSITKA and operando FT-IR measurements, methods scarcely employed in MOF catalysis literature. In combination with density functional theory (DFT) calculations, this work reveals unprecedented insight in the Pt–Zr–MOF interplay that leads to methanol formation during conversion of CO₂/H₂ mixtures at 170 °C and 1–8 bar.

■ EXPERIMENTAL DETAILS

Details of material preparation and standard characterization methods (N₂ adsorption, ¹H NMR, EDX, TGA, TEM, and CO-chemisorption) are provided in the [Supporting Information](#).

Operando FT-IR spectroscopy was performed using a Bruker Vertex70 instrument equipped with a liquid nitrogen-cooled MCT detector. Each spectrum was collected by averaging 64 acquisitions with a resolution of 2 cm⁻¹. The sample (pressed in a self-sustained pellet of approximately 4 mg) was mounted inside a low free-volume cell from AABSPEC (model #CXX), by which pressure, temperature, and gas flow are controllable. Due to the low sample amount, the CO₂ conversion was too low to be determined reliably, and parallel experiments under comparable conditions were performed with the focus on gas-phase analysis (vide infra). The sample was activated at 350 °C (5 °C/min ramp) in 10% H₂/He (10 mL/min) for 4 h and then cooled to 170 °C in 10 mL/min He. The sample was kept under CO₂ hydrogenation (CO₂/H₂ = 1/6, 10 mL/min) reaction conditions for 2 h, before the H₂ flow was exchanged to D₂.

Catalytic testing was performed in a fixed-bed flow setup with a straight stainless steel reactor (7 mm I.D.) operated under 1–8 bar, where effluent species is analyzed with an online Q-MS (Pfeiffer) and GC-TCD-FID (Agilent). The MOF samples were reduced for 4 h at 350 °C (5 °C/min ramp) in 20 mL/(min·0.1 g_{cat}) flow of 10% H₂/Ar under ambient pressure. Following the activation procedure, the reactor was cooled to 240 °C in inert flow and then operated for 4 h reaching steady state under a set of reference conditions (1/6/3 CO₂/H₂/inert, 20 mL/min, 200 mg, τ = 0.01 g_{cat}·min/mL and ambient pressure) before changing conditions. The pre-reduced commercial samples Pt/SiO₂ (abcr), Pt/Al₂O₃ (Chimet), and Pt/C (Chimet) were heated directly to 240 °C under reference conditions, which were maintained until steady state was reached. Dependent on the experimental aim, 0.05–0.2 g of catalyst was tested for CO₂ hydrogenation in the range of 5–25% CO₂, 40–90% H₂, T = 170 °C, p = 1–8 bar, and contact time (τ) = 0.004–0.04 g_{cat}·min/mL. A given set of operating conditions was fixed until steady state was reached and for at least 2 h. During kinetic studies, changes in reaction conditions were performed in a random sequence. Each 3–4 set of conditions were the reference conditions. They showed that the change in catalyst performance was negligible during the kinetic studies. As reported in ref 17, a minor increase in the catalytic activity and change in selectivity is observed for UiO-67-Pt during long-term operation. The same procedure as described above was followed in the H/D exchange experiments but with D₂ instead of H₂. H/D SSITKA experiments were performed by operating the catalysts at steady state under reference conditions and then switching the feed (1/6/3 CO₂/H₂/inert) rapidly to another feed containing D₂ instead of H₂ (1/6/3 CO₂/D₂/inert) using an electronically controlled 4-port 2-way valve. Switches back and forth between the two feeds were performed in intervals of 8 h. ¹³CO₂/¹²CO₂ SSITKA experiments were performed in the same manner. The m/z values traced for each specie in the respective experiments are tabulated in [Table S1](#).

Intermediates and catalyst structures were optimized using DFT calculations. The calculations were carried out using the mixed Gaussian and plane wave method^{31–33} as implemented in CP2K 6.1.^{34,35} The functional was PBE+D3; the atom-centered basis set was DZVP-MOLOPT-SR-GTH,³⁶ and the plane wave kinetic energy cutoff was 360 Ry. Further details are provided in the [Supporting Information](#).

■ RESULTS AND DISCUSSION

The UiO-66 series of Zr–MOFs (UiO-66, -67, -68) consists of Zr₆O₈ nodes connected by dicarboxylate-terminated linkers. The ideal linker-to-node ratio is 6:1, but prior investigations showed that factors like synthesis conditions (type of modulator and concentration, temperature, and crystallization time) and activation conditions may strongly affect this ratio, leading to materials that are commonly referred to as having “missing cluster” or “missing linker” defects, respectively.^{37–43}

(Middle) Pt/ Al_2O_3 . (Right) Pt/ SiO_2 (gray, blue) and Pt/C (black). CO, CH_4 , and CH_3OH selectivity is depicted as squares, circles, and triangles, respectively. $\tau = 0.01 \text{ g}_{cat}/\text{min}/\text{mL}$, $CO_2/H_2/\text{inert} = 1/6/3$. For Pt/ Al_2O_3 , $\tau = 0.02 \text{ g}_{cat}/\text{min}/\text{mL}$.

Missing linker defects may be capped by modulator, anions of the MOF precursor salts, solvent, or OH^-/H_2O pairs.^{39,42,44,45}

The current study was carried out using UiO-67 with 90% biphenyl-4,4'-dicarboxylic acid (BPDC) linkers and 10% 2,2'-bipyridine-5,5'-dicarboxylic acid (BPYDC) linkers, hereafter called UiO-67-Pt. Prior studies have demonstrated that the bipyridine entity in BPYDC is the preferred anchoring site for Pt salts in this MOF.^{17,46–48} In the current study, 1H NMR analysis of digested material showed that the as-synthesized MOF contained 11 BPYDC linkers, 13 benzoic acid ligands, and 2 formic acid ligands, respectively, per 100 BPDC linkers (Table S3). Furthermore, thermogravimetric analysis (TGA) measurements indicated that the as-synthesized MOF had a linker-to-node ratio of 5, suggesting that, in addition to benzoic acid and formic acid, the material contained Cl^- or OH^-/H_2O pairs, adding up to an average of 4 out of 24 Zr coordination sites per Zr node that were not connected to a linker molecule (Table S3).

After wet impregnation with the Pt NP precursor, K_2PtCl_4 , the BPYDC and benzoic acid contents of UiO-67-Pt decreased slightly, while the formic acid content increased to 4 per 100 BPDC linkers (Table S2). Activation in a reducing atmosphere (10% H_2/Ar flow at $350 \text{ }^\circ C$, 1 bar, 4 h) transformed the Pt precursor salt into the active catalytic entity for CO_2 hydrogenation, Pt NPs.^{17,46,48} In the current case, transmission electron microscopy (TEM) investigations after activation showed the presence of Pt NPs homogeneously dispersed within the MOF framework (Figure S5). The Pt NPs supported on UiO-67 have average diameter of $3.6 \pm 0.7 \text{ nm}$ (Figure S5), i.e., larger than the diameter of the tetrahedral (1.2 nm) and octahedral (2.3 nm) cavities of the UiO-67 structure. Most of the Pt NPs displayed a spherical shape; however, careful inspection revealed the presence of NPs with squared borders and an irregular shape, possibly exposing well-defined terraces, after activation and after reaction (Figures S5 and S6). Such features can arise from strong Pt–support

Figure 2. FT-IR spectra of UiO-67-Pt collected during CO₂ hydrogenation (CO₂/H₂ = 1/6, 10 mL/min, 170 °C, 1 bar) at different times (thick black curve for $t = 0$ min, gray scale from darkest to brightest for $0 < t < 120$ min, thick red curve for $t = 120$ min). The left figure shows the magnified spectral region of the $\nu(\text{C-H})$ for formate groups, while the right figure depicts the spectral interval typical for CO linearly adsorbed on metal nanoparticles. Full range spectra are reported in Figure S16.

interaction, and indeed, limited broadening of the Pt NP size distribution was observed after prolonged testing (Figure S6). A schematic illustration of a 3.6 nm Pt particle embedded in an 8 unit cell-enclosed octahedral cavity, mimicking a representative Pt NP observed by TEM, is presented in Scheme 1.

CO₂/H₂ conversion and product selectivity obtained over Pt/C, Pt/SiO₂, Pt/Al₂O₃, and UiO-67-Pt at 170 °C and 1–8 bar are shown in Figure 1. Substantial selectivity differences were observed at similar conversion levels (0.4–1.5%): Over UiO-67-Pt, the methanol selectivity increased from around 3% to 19%, corresponding to a turnover frequency (TOF) of 0.01 s⁻¹, when the pressure increased from 1 to 8 bar (Figure 1). This is, to the best of our knowledge, the second report of significant methanol formation from CO₂ over a Pt-based catalyst where the support alone is inactive in the reaction.²⁸ Under the same conditions, there was only a slight increase in methane selectivity from 1.2% to 1.6%. Over Pt/Al₂O₃, both the methane and methanol selectivity reached 10% under 8 bar pressure (Figure 1). In contrast to UiO-67-Pt, methane selectivity increased substantially with increasing pressure. Finally, over Pt/SiO₂ and Pt/C (Figure 1), CO was the only carbon-containing product observed, in accordance with the theory predictions of Kattel et al. for unsupported Pt NPs.¹⁸ The formation of methanol over UiO-67-Pt points to strong metal–support interactions, as previously reported for Cu NPs embedded in UiO Zr–MOFs^{29,30} and may suggest that the MOF support plays an active role during the reaction, similarly to Al₂O₃ in the WGS and CO₂ hydrogenation reactions.^{8,24,49}

To further assess the role of Pt NPs vs support in CO₂ hydrogenation, steady-state H₂/D₂ exchange experiments were performed under CO₂ hydrogenation conditions over UiO-67-Pt, Pt/Al₂O₃, Pt/SiO₂, UiO-67, and SiO₂. The transient evolution of the HD molecule following a feed switch from CO₂ + H₂ to CO₂ + D₂ is shown in Figure S9. Importantly, the formation of HD (and other products) was observed only over the Pt containing materials but not over the UiO-67 and SiO₂ supports alone, showing that the dissociation of H₂/D₂ only occurs when Pt is present. The amount of HD formed over UiO-67-Pt and Pt/Al₂O₃ was larger than that over Pt/SiO₂ and, in all cases, 1–2 orders of magnitude higher than the amount of exposed Pt atoms in Pt nanoparticles (Table 1). This observation, in combination with the observed HD tailing, strongly suggests H/D exchange with hydroxyl groups on the support materials, either directly by hydrogen spillover to/from the Pt NPs or by H/D exchange with the water molecules formed during the reaction.

Insights into the origin of HD tailing and formed amount over the UiO-67-Pt sample were obtained by a parallel operando FT-IR experiment under comparable conditions (1 bar, 170 °C, CO₂/H₂ = 1/6). When exchanging H₂ for D₂, the sharp signal of Zr– μ_3 -OH at 3669 cm⁻¹³⁹ decreased to zero with time while another equally sharp and intense peak, corresponding to the deuterated species Zr– μ_3 -OD, increased at 2705 cm⁻¹ (Figure S16). Interestingly, the quantification of the molar number of H in HD, $N_{\text{A,HD}}$, yields 1200 μmol H per gram catalyst, which corresponds to about 70% of the theoretical number of Zr– μ_3 -OH groups in the sample. No

(Top left) Normalized intensity of H_2 ($m/z = 2$), HD ($m/z = 3$), H_2O ($m/z = 18$), HDO ($m/z = 19$), CH_3OH ($m/z = 31$), and CH_4 ($m/z = 15$) when switching from $\text{CO}_2 + \text{H}_2$ to $\text{CO}_2 + \text{D}_2$ at $t = 0$. (Top right) Comparison of Zr-DCOO and CH_3OH (inverse) during H/D exchange. (Bottom left) Normalized absorbance of $\text{Zr-}\mu_3\text{-OH}$ (open diamonds), $\text{Zr-}\mu_3\text{-OD}$ (filled diamonds), and deuterated formate (triangles) during the exchange of H_2 to D_2 at steady-state CO_2 hydrogenation. $\text{CO}_2/\text{H}_2(\text{D}_2) = 1/6$, 10 mL/min, 170 °C, 1 bar. (Bottom right) Normalized intensity of Kr ($m/z = 84$), $^{13}\text{CO}_2$ ($m/z = 45$), ^{13}CO ($m/z = 29$), $^{13}\text{CD}_4$ ($m/z = 21$), and $^{13}\text{CD}_3\text{OD}$ ($m/z = 35$) products when switching from $^{13}\text{CO}_2 + \text{D}_2$ to $^{12}\text{CO}_2 + \text{D}_2$ at $t = 0$. $T = 170$ °C, 1 bar, $\tau = 0.01$ g_{cat}·min/mL.

other indication of H/D exchange (neither on Pt nor in linkers) was found from the FT-IR experiments. A more detailed description of the spectra obtained during FT-IR experiments over UiO-67-Pt, including the hydroxyl group region and the C–H bonds present in the aromatic linkers (the carboxylates region is omitted as it is out of scale), is given in the supporting section (Figure S16). It is important to note that the chemical integrity of the catalyst is preserved during the reaction, and changes in the spectra are therefore caused by reaction products interacting with the sample. The most evident change is caused by the progressive increase of CO on the Pt nanoparticles (Figure 2). The shape and frequency of this signal is compatible with carbonyls linearly adsorbed on Pt atoms at the surface of the NPs, as we already addressed in our previous study on an analogous material.¹⁷ The size of the particles (3.6 nm) and the temperature (170 °C) justify the absence of bridged carbonyl species at lower frequencies. Changes in one of the smaller peaks in the IR spectra are the most novel observation of this study: the peak arising at 2745 cm^{-1} (Figure 2) is due to the appearance of bidentate formate groups³⁹ (which, notably, are absent after activation; see Figure 2), most likely coming from the progressive process of the CO_2 reduction. The frequency of this weak feature is compatible with the $\nu_s(\text{COO}) + \delta(\text{CH})$ vibration of bidentate formates directly connected to open Zr sites of the Zr nodes in the MOF framework.^{39,50,51} Further bands associated with formate are visible in the top part of Figure S16 in the 3000–2800 cm^{-1} region. The spectrum of the sample collected during CO_2

hydrogenation after the subtraction of the activated one (Figure S17) highlights the formation of four additional bands at 2910, 2888, 2868, and 2854 cm^{-1} , ascribable to various formate species at the Zr node.³⁹ This is, to the best of our knowledge, the first report of formate formation at the MOF Zr node under CO_2 hydrogenation reaction conditions.

The importance of these moieties is even more evident, thanks to the isotopic exchange experiment between H_2 and D_2 . When exchanging H_2 for D_2 , the signals of the formate groups shifted to lower wavenumbers; the signals in the 2950–2850 cm^{-1} region shifted to the region of the CO_2 roto-vibrational profile and are therefore not detectable. Conversely, the band at 2745 cm^{-1} shifted to 2168 cm^{-1} ³⁹ (Figure S16) and the intensity vastly increased as compared to the H-analogue ($I_{\text{HCOO}}/I_{\text{DCOO}} \approx 0.02$). The intensity increase indicates an inverse kinetic isotope effect, although possible differences in the extinction coefficient of the two species cannot be excluded. Importantly, a corresponding, gradual increase in methanol production rate was observed upon H_2/D_2 exchange under steady-state CO_2 hydrogenation conditions (Figure S14). At isotope equilibration, this difference in H- and D-methanol production rates corresponds to an inverse kinetic isotope effect (KIE), $r_{\text{H}}/r_{\text{D}} = 0.36$. Moreover, the temporal scale of exchange was very similar for the formate species and for methanol in the parallel H_2/D_2 exchange experiments performed in the FT-IR transmission cell and the test setup, respectively (Figure 3) (see the Experimental Details for more information). Together, these experiments provide firm

Scheme 2. Schematic Presentation of the Postulated Reaction Mechanism of CO₂ Hydrogenation to the Formate Intermediate in CH₃OH Formation at the Pt–Zr Node Interface

evidence that the Zr–formate species is a key intermediate in the methanol formation path.

Furthermore, during a complementary (¹³CO₂ + D₂)/(¹²CO₂ + D₂) exchange experiment (Figure 3), ¹³CD₃OD decreased steadily to zero in about 200 min, similarly to what was observed for formate and methanol during the H₂/D₂ switch. The slope of the normalized intensity of methanol in a semi-logarithmic plot (Figure S15) is inversely proportional to the mean surface residence time ($-1/\tau_{\text{res}}$) of intermediates leading to the formation of methanol (Table 3) and is characteristic of the formation from a single pool of intermediates.⁵²

Overall, the transient experiments provide firm evidence that formate species, attached to the Zr nodes in a bidentate configuration, are formed by H transfer from an adjacent Pt NP. The inverse KIE observed for methanol formation ($r_{\text{H}}/r_{\text{D}} = 0.36$) is a signature of reactions where the rate limiting step involves hydrogen addition to an sp- or sp²-hybridized carbon, leading to a hybridization change (sp to sp² or sp² to sp³).^{10,53} CO₂ hydrogenation to methanol via formate species involves two such steps: CO₂ hydrogenation to form formate, and formate hydrogenation to (probably) form dioxymethylene.⁵⁴ The observation of abundant formate species by FT-IR further suggests that hydrogenation of the formate species is the rate limiting step of methanol formation in UiO-67-Pt. Previously, an inverse KIE (albeit not as strong as in our case) was reported for CO₂ to methanol over Cu/ZnO/Al₂O₃, Cu/SiO₂, Cu/MgO, and Pd/SiO₂.¹⁰ In that case, DFT calculations predicted an inverse KIE for hydrogenation of the formate species, in line with our results. A schematic presentation of the postulated reaction mechanism is shown in Scheme 2.

The integration of the ¹³C/¹²C transient response of methanol showed an intermediate species concentration of 23 μmol/g (Table 3), i.e., close to half the amount of Pt surface species estimated for the ensemble of Pt NPs identified by TEM (3.6 nm average diameter, Table 1). The schematic illustration of such a particle embedded in the MOF structure suggests that the average Pt NP contains 640 surface Pt sites and is surrounded by 32 Zr nodes that have a total of 224 Zr sites accessible for coordination at the Pt–MOF interface, corresponding to 112 bidentate formate species (Scheme 1, Figure 2). These numbers yield a formate-to-Pt surface site ratio of 112:640 (0.2), substantially lower than the estimated 23:55 (0.4) ratio from transient experiments.

Importantly, the numbers imply that additional Zr sites are available to formate formation around each Pt NP. In this respect, we hypothesized that Zr sites might become accessible by breaking Zr–linker bonds, either during Pt NP formation or during the catalytic reaction. The hypotheses were investigated by periodic DFT calculations (see the Experimental Details section for a brief description of the methodology and the

Supporting Information for further computational details and model construction). A Pt₈₉ NP occupying the tetrahedral cavity of UiO-67 (Figure S18), Pt₈₉^{tet}, was found to be an adequate model, justified by the assumption that the interface between the Pt NP and the linker/Zr node is similar when the NP has a diameter of 3.6 nm or ≈1 nm.

In the perfect MOF structure, all 24 coordination sites of each Zr node are occupied by the carboxylate groups of the linker molecules (L). We first investigated the opening of such sites and computed the free energy profile of the system when a linker decoordinates from the node and slides along the Pt NP surface (Figures 4 and S22). Decoordination of the linker presumably occurs via $\sigma(\text{Csp}^2\text{--Csp}^2)$ bond rotation at the O₂C–C(Aryl) fragment, which generally involves low energy barriers. In Figure 4, L^X and O₂^X indicates the coordination mode of the linker or formate oxygen to the Zr node (X = number of Zr–O bonds) and * indicates the atom adsorbed to the Pt₈₉ NP. These calculations showed that it is unfavorable to open two Zr sites ($\Delta G(\text{L}^2 \rightarrow \text{L}^0) = 16$ kJ/mol), while opening one Zr site is favorable ($\Delta G(\text{L}^2 \rightarrow \text{L}^1) = -54$ kJ/mol), indicating that the interaction with the NP weakens the node-linker Zr–O bonds, favoring the formation of vacant sites. Considering next the catalytic reaction, the first step of formate formation is the adsorption of a CO₂ molecule, which was found to coordinate its C atom to the Pt surface and the O atom to the opened Zr site ($\Delta G_{\text{ads}}(\text{L}^1 + \text{CO}_2 \rightarrow \text{L}^1\text{--C}^*\text{O}_2^1) = -20$ kJ/mol) (Figure 4). When the formate formation pathway is continued from the L¹–C*O₂¹ intermediate, the two subsequent intermediates, L¹–C*O₂¹ + 2H*, $\Delta G(\text{L}^1 + \text{CO}_2 + \text{H}_2 \rightarrow \text{L}^1\text{--C}^*\text{O}_2^1 + 2\text{H}^*) = -144$ kJ/mol, and L¹–HCO₂¹ + H*, $\Delta G(\text{L}^2 + \text{CO}_2 + \text{H}_2 \rightarrow \text{L}^1\text{--HCO}_2^1 + \text{H}^*) = -107$ kJ/mol, correspond to H₂ adsorption on the Pt NP and a formate + hydride species, respectively (Figure 4). The H₂ adsorption is exergonic by –70 kJ/mol, and the subsequent H transfer to the C atom of CO₂ is endergonic by 37 kJ/mol. Interestingly, the transformation from L¹–HCO₂¹ + H* to L⁰–HCO₂² + H*, where the formate species is coordinated to two Zr sites is highly endergonic, $\Delta G_{\text{t}}(\text{L}^1\text{--HCO}_2^1 + \text{H}^* \rightarrow \text{L}^0\text{--HCO}_2^2 + \text{H}^*) = 78$ kJ/mol. The transformation from L¹–HCO₂¹ + H* to L⁰–HCO₂² + H* comprises two structural changes: (i) the formate moiety goes from being coordinating to one Zr site to being coordinated to two Zr sites; (ii) the linker decoordinates from one Zr site, opening two Zr sites. To estimate the contribution to the free energy change, $\Delta G(\text{L}^1\text{--HCO}_2^1 + \text{H}^* \rightarrow \text{L}^0\text{--HCO}_2^2 + \text{H}^*)$, of (i) and (ii), a computational experiment was performed: while keeping the linker in a “completely open position” (L⁰), the formate moiety was oriented to its Zr-monodentate configuration HCO₂¹. This resulted in a potential energy increase of 45 kJ/mol.

These results indicate that the coordination of formate by one Zr–O bond (monodentate) is thermodynamically

Figure 4. 3D representations of the intermediates of the reaction pathway toward the formation of the formate species coordinated to two Zr sites. Values are free energies in kJ/mol. L^X and O_2^X indicate the coordination number of the linker and formate to the Zr node and *, the atom adsorbed to Pt. O, C, and H atoms from CO_2 and H_2 are in pink, black, and green, and for the linker, they are in red, gray, and white.

preferred in nodes initially saturated by linkers (L^2), while the coordination of formate by two Zr–O bonds (bidentate) is thermodynamically preferred in nodes initially having lost some linkers (L^0). Therefore, the observation of the latter coordination mode of formate by FT-IR suggests that these

species have been generated in Zr nodes with empty coordination sites at the start of the reaction, as represented in Scheme 2.

It was then explored whether the growth of the Pt NP during activation could cause the formation of such Zr nodes with open coordination sites. Insight into this possibility was obtained by computing the free energy of the Pt particle growth from $\text{Pt}_{55}^{\text{tet}}$ to $\text{Pt}_{89}^{\text{tet}}$. These calculations showed that the reaction free energy of the system decreases as the Pt NP grows, and the decrease in energy will eventually exceed the energy loss of linker detachment (Figures S19–S21). Thus, during the nanoparticle growth, linkers will detach from the Zr nodes, and the Zr nodes will decorate the growing Pt nanoparticle. Returning to Scheme 1, the number of Zr nodes that needs to be removed from a perfect Pt NP is a minimum of 6. The corresponding number of additional bidentate formate sites is 54. In combination with the 112 formate sites of the surrounding framework bound nodes, this yields a total number of formate sites of 166 and a formate-to-Pt surface atom ratio of 0.3, in reasonable agreement with the experimentally observed numbers.

Support for the computational results were found from online mass spectrometry (MS) measurements performed during activation in a 10% H_2/Ar atmosphere at 350 °C. The MS data revealed traces of phenyl-containing fragments in the effluent gas, suggesting that modulator and/or linker molecules desorbed from the material during Pt NP formation (Figure S8). The crystallographic features of the material were unchanged (Figures S2, S5, and S6) and the BPYDC/BPDC ratio remained constant during subsequent testing (Table S2). Furthermore, no linker fragments were observed during a second activation of UiO-67-Pt after testing, in line with the excellent catalyst stability observed under the reaction conditions.

Having established the importance of the Zr nodes and formate intermediates for methanol formation over UiO-67-Pt, the next issue is whether methanol formation could be decoupled from CO and CH_4 formation, hence, optionally leading to higher methanol selectivity. To this end, we first turn to classical kinetic experiments.

Contact time variation experiments, under otherwise constant conditions, showed that methanol selectivity is constant when CO_2 conversion increases, suggesting that it is a primary reaction product (Figure 5). Conversely, methane

Figure 5. Contact time variation during CO_2 hydrogenation to CO (squares), CH_4 (circles), and CH_3OH (triangles) at 170 °C, 1 bar, $\text{CO}_2/\text{H}_2/\text{He} = 1/6/3$, and $\tau = 0.004\text{--}0.04$ $\text{g}_{\text{cat}} \cdot \text{min}/\text{mL}$. (Left) Selectivity versus conversion. (Right) Rate of product formation versus contact time.

selectivity increases with increasing CO₂ conversion, while CO selectivity decreases, suggesting that CH₄ is mainly a secondary product, formed via CO. The latter result is in accordance with our previous studies of an analogous catalyst at higher temperature.¹⁷

Next, partial pressure variation experiments were performed in order to assess the reaction orders for each product. This assessment was complicated by the decreased formation rate of all the products with increasing contact time (Figure 5), indicating a strong adsorption of one or several reaction products, thereby poisoning the active site(s).^{10,19} Indeed, when the rate decrease was correlated with the partial pressures of the majority products, CO and H₂O, all products had a reaction order close to negative 1 in p(CO + H₂O) and CH₄ was slightly less negative (Figure S10 and Table 2). On

Table 2. Reaction Orders in Total Pressure (p_{total}) and in p_{H_2} , p_{CO_2} , and $p(\text{CO} + \text{H}_2\text{O})$ (1 bar) for the Rate of Conversion (X) and CO, CH₄, and CH₃OH Formation at 170 °C over UiO-67-Pt

| p_i | X | CO | CH ₄ | CH ₃ OH |
|------------------------------------|------|------|-----------------|--------------------|
| p_{total} | 0.1 | 0 | 0.3 | 1.1 |

| H ₂ ^b | 0.2 | 0.2 | 0.9 | 1.7 |
| CO ₂ ^b | 0.9 | 0.9 | 0.1 | 0.7 |

^aEstimated from contact time variation experiments (Figures 5 and S10). The reaction orders represent the average of two experiments.

^bReaction orders when taking into account variable pCO and pH₂O in the reactor.

the basis of the FT-IR results reported above, it was shown that CO adsorbed on Pt (2042 cm⁻¹)¹⁷ dominates the Pt surface under the respective reaction conditions and CO was assessed as the main contributor to the inhibition, likely suppressing the coverage in H by competitive adsorption.⁸ When taking into account the variable concentration of CO and H₂O, positive reaction orders in pH₂ and pCO₂ were observed for all products but with substantial differences (Table 2).

Considering first the majority product, CO, its formation rate depends strongly on pCO₂ but less on pH₂ (Table 2). Furthermore, no KIE was observed for CO during the (CO₂ + H₂)/(CO₂ + D₂) transient experiment (Table S5 and Figure S14), showing that breaking or making H–H or H–O bonds (which would otherwise lead to a primary KIE)^{10,55} is not rate-determining for CO formation under the conditions studied here. Finally, the number of surface intermediates leading to CO formation and their mean residence time were calculated from the ¹³C/¹²C transients (Table 3 and Figure 3). The normalized ¹³CO signal rapidly decreased to around 0.05 within the first 15 min and then slowly reached zero in the following 150 min. It is interesting to note that the number of

Table 3. Mean Surface Residence Times τ_{res} and the Number N_{ads} of Surface Intermediates Leading to the Formation of ¹³CO, ¹³CD₄, and ¹³CD₃OD at 170 °C (1 bar)^a

| τ_{res} (s) | 0.5 × 10 ³ | 2.1 × 10 ³ | 3.8 × 10 ³ |

^aCalculated from integration of the curves in Figure 3 and the isotope-independent steady-state reaction rates.

surface intermediates leading to CO formation represents half of the Pt surface atoms in Pt NPs, estimated from TEM measurements (Table 1 vs Table 3). This observation, in combination with the partial coverage of the Pt NPs by Zr nodes (and linkers), the inhibiting effect of CO, the high predicted barrier of CO desorption from Pt,¹⁸ and the observation of a positive correlation between facile CO desorption and the rate of CO formation in our previous study¹⁷ strongly suggest CO desorption as the rate-limiting step in the RWGS reaction over UiO-67-Pt.

Turning next to the methane formation rate, it depends strongly on pH₂ and weakly on pCO₂ (Table 2). When one considers the high coverage of CO as well as the presumed indirect formation of methane via CO, this result is not surprising. In the (CO₂ + H₂)/(CO₂ + D₂) transient experiment, an inverse KIE of 0.6, i.e., intermediate between CO (KIE = 1) and methanol (KIE = 0.36), was observed for methane (Table S5 and Figure S14). Intriguingly, the inverse KIE was installed within the 15 min resolution of the gas analysis; hence, it was much more rapid than the transient behavior of methanol (Figure S14). Thus, the rate-determining step of methane formation involves bonding with hydrogen,^{55–58} but the rate-determining step is not the same as for methanol formation. Indeed, the much more rapid transient behavior of methane compared to formate disqualifies formate as a significant intermediate to methane formation. This result implies that, except for hydrogen activation, methane formation is mechanistically decoupled from methanol formation. The normalized CH₄ formation rate (represented by the $m/z = 15$ signal of CH₃) also decreases rapidly to zero (comparable to H₂) during the H/D exchange (Figure 3). Due to their mass overlap with the much more abundant water fragments, the time evolution of partially exchanged methane/methyl species could not be followed. The transient behavior of methane during the ¹³C/¹²C switch (Figure 3) was markedly different from that observed in the H/D transient: The normalized ¹³CD₄ formation rate decreased to 0.5 during the first 7 min and then slowly to zero in the following 160 min. This distinct shape of the isotope transient indicates methane formation from two pools in parallel:^{52,59} one rapidly converted to products, and the other converted more slowly. The integration of the transient curve showed that the number of surface intermediates leading to methane formation is low (Table 3). Moreover, about 3% of the methane-forming intermediates react fast and is responsible for about 50% of the steady-state methane formation rate, while the other 97% react slowly (Table 3 and Figure S15).

Returning finally to methanol, its formation depends strongly on both reactant partial pressures, in line with the observation that it is a primary product formed independently of CO (Figure 5). The ¹³C/¹²C transient experiment shows that methanol is formed from a similar number of surface intermediates as CO, but their turnover rate is much slower, hence leading to the 9% methanol selectivity observed under the respective conditions (Table 3).

Finally, the noncarbon products HD, H₂O, and HDO exhibited slow or partially slow transient responses (Figure 3). HD has a sharp initial peak with considerable tailing over the course of the following hour, indicating the formation from parallel pools and/or exchange with hydrogen-containing surface species.⁶⁰ H₂O showed transient characteristics suggestive of parallel pools, similar to CO and CH₄, and the HDO signal increased rapidly to a maximum within a few

minutes and then slowly decreased over the course of 2 h, closely following the methanol signal. The long surface lifetime of these products is indicative of a long-lived source of H participating in their formation, presumably also in the formation of methanol. Interestingly, quantification of the mol H in HD, H₂O, HDO, and CH₃OH yields 1500 μmol H per gram catalyst, which corresponds to about 80% of the theoretical amount of Zr-μ₃-OH groups in the sample (HD accounts for 70%, as reported above).

CONCLUSION

Mechanistic aspects of CO₂ hydrogenation over UiO-67-Pt and the role of the UiO-67 framework have been investigated in detail by the employment of steady-state and transient kinetic studies, coupled with operando infrared spectroscopy and DFT modeling.

It was observed that Pt NPs embedded in the MOF structure are responsible for hydrogen activation and that formate species are formed at the Zr nodes by the reaction between adsorbed CO₂ and hydrogen spillover from an adjacent Pt NP. These results demonstrate that the Pt NPs strongly interact with defect Zr nodes during the reaction and, hence, that Zr nodes decorate the surface of the Pt NPs. Formate species are the most abundant intermediates in the reaction path to methanol, and transient results suggest that formate hydrogenation is the rate-limiting step of methanol formation. Importantly, the abundance of formate species is limited by the number of Zr sites made available by linker detachment due to Pt NP growth during catalyst activation.

CO and methane formation are mechanistically separated from methanol formation, except for the hydrogen dissociation step. The main route to methane formation is proposed as CO hydrogenation. Moreover, the presented data are consistent with CO desorption being the rate limiting step of the reverse water gas shift reaction over UiO-67-Pt.
